Abstract

Data-driven methods of simulating a crowd of virtual humans that exhibit behaviors imitating real human crowds play an important role in crowd simulation. In this paper, we propose a Bayesian framework for the extraction of real human's behaviors which exhibit interactions in their daily life using multiple fixed cameras. The described Markov chain Monte Carlo particle filter can effectively deal with interacting targets which are influenced by the proximity and behaviors of other targets. In this paper, we use a Markov random field motion prior combining with a federate filter algorithm which treats the observations discriminatorily to substantially improve the tracking of a fixed number of interacting targets. Simultaneously, we replace the traditional importance sampling step with MCMC sampling step to get over the vast computational requirements for large numbers of targets. i.e., we focus on the data fusion and the behavior recognition process. Finally, experimental results demonstrate that the proposed Bayesian framework deals efficiently and effectively with extractions of interacting behavior.

Keywords: behavior extraction, MCMC-based particle filter, Markov random field motion prior, federate filter

1. Introduction

The behaviors of human crowds in the real world characterized with trajectory, velocity, and interaction vary significantly depending on time, place, and many other factors [1]. This work is concerned with the problem of behavior extraction from sequential images recorded by multiple cameras. The extracted behaviors can be used to produce many desired styles in data-driven methods of simulating the crowd. Learning human behaviors from videos is a challenging problem because the motion of each individual is influenced by many factors the most important one of which is the interactions between proximate targets. We assume that each target motion in the video is Markovian and targets do not overlap with each other vertically. Our objective is to correctly detect entering and leaving targets and obtain a

* E-mail address: mengshuqin1984@163.com

record of the trajectories of targets over time, maintaining a correct, unique identification for each target throughout. Tracking multiple targets which are identical in appearance becomes significantly more challenging when the targets interact. Methods that appropriately deal with this difficult issue are useful for applications where many interacting targets need to be tracked over time. In particular, they have important implications for vision-based tracking of human behaviors which can be used to improve the realism of crowd simulation [1,2].

There is a great potential to extract the real people's behaviors from video sequences by use of computer vision algorithms. A number of classical approaches have been proposed to the problem of multiple hypothesis tracker (MHT) and the joint probabilistic data association filter (JPDAF) [2]. These multi-target tracking algorithms which including nearest neighbor tracking in [3], the MHT in [4], and the JPDAF in [5] and [6] have been extensively used in the context of computer vision. However, the foregoing methods do not take into account targets' interactions. There is an abundance of literature devoted to the PF approach to multi-object tracking (MOT). Methods using a single-object state-space model are usually computationally inexpensive. A shortcoming of this approach is that identities and interactions between objects can not be easily modeled in formal (and algorithmic) terms [7]. Recently, A joint state-space model was proposed to efficiently track a fixed number of interacting objects using a sampling method that combines a PF formulation with MCMC sampling in [2]. This approach addressed the problem of interaction as well, by defining a pair-wise Markov Random Field (MRF) prior in the dynamical model, which is more computationally tractable than other methods [8]. However, the aforementioned approaches only use a fixed camera to extract the features of targets.

Although multiple object tracking has been extensively studied in computer vision, automatic behavior extraction is still a challenge in practice. In this paper we address the problem of interacting targets by employing federate PF on the basis of previous studies. The federated filter fused the outputs of local filters to generate the global estimation. The behaviors of interacting targets are modeled by a motion model based on MRF. Considering the computational complexity of federate filter, we use MCMC-based sampling step to replace traditional importance sampling. And the observation model is represented by binary information picked-up from background subtraction, together with the foreground and background color features. A specific disposal to the motion model and observation model is proposed to solve the problem of information fusion. In our algorithm, the MCMC-based filter combining MRF dynamical model serves as the local filter, the federated filter is used to fuse outputs of all local filters, and the global filter result is obtained. The advantages of our approach are obvious that it combines the benefits of MCMC-based filter and federate filter, the most valuable one of which is our approach's powerful fault detection, isolation and recovery abilities.

The remainder of this paper is organized as follows. Section 2 reviews the work related to Bayesian multi-object tracking combining with the dynamic model of interacting targets. Section 3 discusses the MCMC-based sampling step. Section 4 covers, respectively, the fusion of data from multiple cameras. Section 5 provide some remarkable experimental validations and conclusions

2. Bayesian multi-object tracking and interactive model

2.1. traditional independent PF

Bayes filter is a classical approach in tracking multiple targets. The posterior distribution $P(X_{i,t} | Z_j^t)$, $i \in 1 \dots n$; $j \in 1 \dots m$ is recursively updated give all observations $Z_j^t = \{Z_j^1 \dots Z_j^t\}$ up to and including time t according to (1). n is the number of targets, and m is the number of cameras.

$$P(X_{i,t} | Z_j^t) = kP(Z_j^t | X_{i,t}) \int_{X_{i,t-1}} P(X_{i,t} | X_{i,t-1}) P(X_{i,t-1} | Z_j^{t-1}) \quad (1)$$

where $P(X_{i,t} | X_{i,t-1})$ is the dynamical motion model that predicts the state $X_{i,t}$ of the i -th targets at time t given the previous state $X_{i,t-1}$.

The likelihood $P(Z_j^t | X_{i,t})$ denotes the observation likelihood, the probability we observed the j -th observation given the state $X_{i,t-1}$ at t . And k is the normalization constant.

Behavior extraction is a non-linear, non-Gaussian problem, in which PFs are accomplished. The essence of filtering distribution is that the posterior at the previous time step is approximated by a set of weighted particles $\{(X_{i,t-1}^{(r)}, w_{i,t-1}^{(r)})\}$, where $X_{i,t}^{(r)}$ and $w_{i,t}^{(r)}$ denote the r -th sample and its associated weight at each time-step. We can rewrite (1) as:

$$P(X_{i,t} | Z_j^t) \approx kP(Z_j^t | X_{i,t}) \sum_r w_{i,t-1}^{(r)} P(X_{i,t} | X_{i,t-1}^{(r)}) \quad (2)$$

using importance sampling. And for the current time-step we draw N samples $X_{i,t}^{(s)}$ from a proposal distribution

$$X_{i,t}^{(s)} \sqcup q(X_{i,t}) = \sum_r w_{i,t-1}^{(r)} P(X_{i,t} | X_{i,t-1}^{(r)}) \quad (3)$$

The weights are then computed as $w_{i,t}^{(r)} \propto P(Z_j^t | X_{i,t}^{(r)})$

2.2. Dynamic model for interactive targets

Our approach to model interactive targets introduces a capable motion model, based on MRFs. The MRF is defined on an undirected graph (V, E) , of which interactive targets define the nodes. Interactions are defined on contiguity cliques. The state of one target is influenced by the constraints placed by the MRF prior (Fig. 1). The pair-wise interaction between two neighbours can be written as:

$$P(X_t | X_{t-1}) \propto \prod_i P(X_{i,t} | X_{i,t-1}) \prod_{i,j \in E} \phi(X_{i,t} | X_{j,t}) \quad (4)$$

Where $\phi(X_{i,t} | X_{j,t})$ are the pair-wise interaction potentials. Since it is easier to specify the interaction potential in the log domain, $\phi(X_{i,t} | X_{j,t})$ is expressed by means of the Gibbs distribution [2]:

$$\phi(X_{i,t} | X_{j,t}) \propto \exp(-g(X_{i,t}, X_{j,t})) \quad (5)$$

where $g(X_{i,t}, X_{j,t})$ is a penalty function. In the application of behaviour extraction, $g(X_{i,t}, X_{j,t})$ depends only on the number of pixel overlap between the targets' body rectangle (Fig. 2).

Figure 1 Interaction potentials. (Left : observe from horizontal camera) A pair-wise MRF is built among individual pairs. Proximate individuals influence each other stronger than distant individuals. (Right : observe from vertical camera)

Figure 2 Overlapping individuals. (Left : observe from horizontal camera) A pair-wise MRF is built among individual pairs.

Individuals ($X_{3,t}, X_{4,t}$) overlapping with each other are penalized. (Right : observe from vertical camera)

In [7], the observations only come from horizontal cameras. It will bring misjudgements on estimating the overlapping region when two individuals overlap from horizontal angle of view, but the distance between them goes beyond each other's influence area. In [2], although the observations come from vertical cameras, it aims at ants' behaviors. Because the ants can overlap with each other vertically, this phenomenon rarely happens in human beings. This paper estimates the penalty function depending on vertical and horizontal observations, e.g., the vertical observations revise the judgement. So when we design the federate filters, vertical observations and its' observation model are regarded as the master filter.

3. An MCMC-based MRF particle filter

MCMC-based PFs generate a sequence of samples from a Markov chain of which the stationary distribution corresponds to the target distribution after an adequate time [7]. In fact, this section pays attention to replacing the inefficient importance sampling step of a straightforward PF implementation by a more efficient MCMC sampling step, which drastically improves tracking results and reduces the computation burden. Instead of using weighted samples obtained using importance sampling, the posterior is represented as a set of unweighted samples. Thereby, on the basis of (2) ~ (4), we obtain (6):

$$P(X_t | Z_j^t) \approx k P(Z_j^t | X_{i,t}) \prod_{i,j \in E} \exp(-g(X_{i,t}, X_{j,t})) \sum_r \prod_i P(X_{i,t} | X_{i,t-1}^{(r)}) \quad (6)$$

A Metropolis-Hastings (MH) sampler is used to sample in MCMC techniques at each time step to generate a set of samples from a proposal distribution density $q(X^* | X)$, where X and X^* denote the current and proposed states. The acceptance ration for the j -th observation is computed as:

$$\alpha = \min \left(1, \frac{p(X_t^* | Z_j^t) q(X_t | X_t^*)}{p(X_t | Z_j^t) q(X_t^* | X_t)} \right) \quad (7)$$

In MH algorithm, if $\alpha \geq 1$, $X_{i,t}^*$ is accepted as the new particle. Otherwise, X^* is only accepted with probability α , and reject otherwise. In the latter case, $X_{i,t}$ is accepted as the new particle. The proposal density q is computed as [2]:

$$q(X_t^* | X_t) = \begin{cases} \frac{1}{n} q(X_{i,t}^* | X_{i,t}) & \text{if } X_{-i,t}^* = X_{-i,t} \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

The step of MCMC-based PF which is familiar to many related researchers is not list in this paper.

4. Framework of data fusion

The structure of federate MCMC-based MRF particle filtering is show in Fig.3, in which vertical observations and horizontal ones are treated discriminatorily.

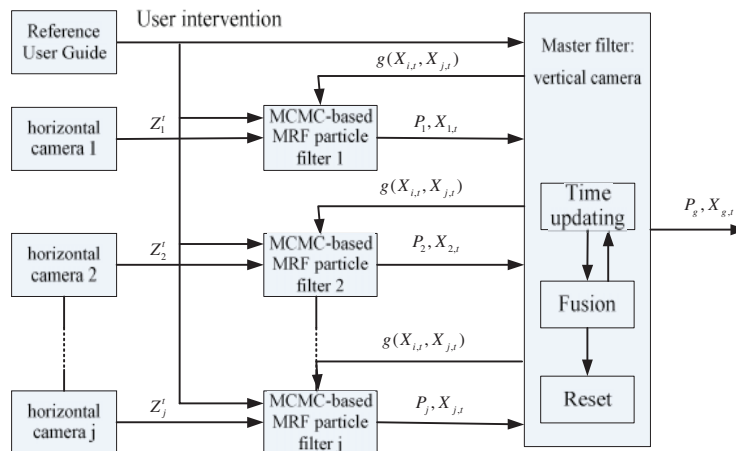

Fig.3 The structure of federate MCMC-based MRF PF

Federate MCMC-based MRF PF which is composed of MCMC-based MRF PF and the federated filter is based on the nonlinear state model and the information fusion theory. First of all, MCMC-based MRF PF is employed to estimate local filters and their estimation results are acquired. Then, local filters' estimations are fused to acquire the system's global optimal estimate by the master filter [9].

In the structure of Federate MCMC-based MRF PF, local filters run in parallel and accept external sensor data from horizontal cameras. Outputs of local filters are fused via master filter which provides feedbacks $g(X_{i,t}, X_{j,t})$ to local filters. The feedbacks are closely related to the observations from vertical cameras. Estimates yielded by the federated filter X_g are globally optimal or conservatively suboptimal [10].

In addition, our system offers a chance for user interventions which provide a putting right capacity from users. Our user guide allows the user to refine the (possibly flawed) tracking result, for example, the "hijacking" problem.

5. Experimental Validation and Conclusion

We adopt observations which are binary and color measurements proposed in [7], $Z_j^t = (Z_{j,t}^b, Z_{j,t}^c)$. Binary observations $Z_{j,t}^b$ are extracted using background removal techniques. Accordingly, the color observations $Z_{j,t}^c$ are made in HS space. The observation likelihood is defined as:

$$p(Z_j^t | X_t) = p(Z_{j,t}^c | Z_{j,t}^b, X_t) p(Z_{j,t}^b | X_t) \quad (9)$$

For an image sequence divided into foreground and background pixels, the observations can be expressed as $Z_{j,t} = (Z_{j,t}^F, Z_{j,t}^B)$, then $p(Z_{j,t}^c | Z_{j,t}^b, X_t) = p(Z_{j,t}^{c,F} | Z_{j,t}^{b,F}, X_t) p(Z_{j,t}^{c,B} | Z_{j,t}^{b,B}, X_t)$ and $p(Z_{j,t}^b | X_t) = p(Z_{j,t}^{b,F} | X_t) p(Z_{j,t}^{b,B} | X_t)$.

Table 1 is the experimental results which are compared with MCMC-based MRF PF algorithms.

Table 1. experimental results			
Tracker	samples	failures	Per target error in pixel
MCMC	1000	29	2.01 ± 0.82
MCMC	2000	26	1.86 ± 0.94
federate MCMC-based MRF PF	1000	20	1.95 ± 0.73
federate MCMC-based MRF PF	2000	15	1.29 ± 0.81

The experimental results show that federate MCMC-based MRF PF not only tracks the targets in low errors, but has the virtue of fault detection, isolation and recovery capability. So it's feasible to solve the problem of behavior extraction of interacting pedestrians by way of vertical and horizontal cameras..

After successfully tracking the moving pedestrian from one frame to another in video sequences, the problem of understanding and describing people's behaviors, especially the group interaction behaviors, follows naturally. Behavior understanding involves the analysis and recognition of motion patterns. The high-level description of behaviors like actions and interactions involves the methods of DTW, FSM, HMM, TDNN, natural language description of behaviors, etc [11]. If this problem is breached, the simulation of interpersonal behavior in autonomous pedestrians will gain a great improvement.
